ABSTRACT

We report on a user study evaluating Redirected Free Exploration with Distractors (RFED), a large-scale, real-walking, locomotion interface, by comparing it to Walking-in-Place (WIP) and Joystick (JS), two common locomotion interfaces. The between-subjects study compared navigation ability in RFED, WIP, and JS interfaces in VEs that are more than two times the dimensions of the tracked space. The interfaces were evaluated based on navigation and wayfinding metrics and results suggest that participants using RFED were significantly better at navigating and wayfinding through virtual mazes than participants using walking-in-place and joystick interfaces. Participants traveled shorter distances, made fewer wrong turns, pointed to hidden targets more accurately and more quickly, and were able to place and label targets on maps more accurately. Moreover, RFED participants were able to more accurately estimate VE size.

1 INTRODUCTION

Navigation is the combination of wayfinding and locomotion and as such is both cognitive and physical. Wayfinding is building and maintaining a cognitive map and it is used to determine how to get from one location to another, while locomotion is moving, physically or virtually, between two locations [4]. In the real world people often locomote by walking. Walking is simple and natural, and enables people not only to move between locations, but also to develop cognitive maps, or mental representations, of environments.

People navigate every day in the real world without problem, however users navigating VEs often become disoriented and frustrated, and find it challenging to transfer spatial knowledge acquired in the VE to the real world [5, 7, 8, 17]. Navigation is important for VE applications where spatial understanding of the VE must transfer to the real world, such as exploring virtual cities, training ground troops, or visiting virtual models of houses.

Real-walking locomotion interfaces are believed to enable better user navigation, are more natural, and produce a higher sense of presence than other locomotion interfaces [25, 28]. In this paper we further develop the real-walking locomotion interface, Redirected Free Exploration with Distractors (RFED) which was first

presented in [16]. RFED is for head-mounted display (HMD) users who are moving through VEs on foot, i.e., walking. Additionally, we demonstrate the effectiveness of RFED to enable free exploration in large scale VEs.

A common argument against redirection and distractors is a potential increase in cognitive load, disorientation, and simulator sickness. We demonstrate through a between-subjects user study that users perform significantly better on navigation and wayfinding metrics with RFED than with joystick and walking-in-place locomotion interfaces. RFED participants traveled shorter distances, made fewer wrong turns, pointed to hidden targets more accurately and more quickly, and were able to place and label targets on maps more accurately than both joystick and walking-in-place participants. No significant difference in either presence or simulator sickness was found between RFED, WIP, and JS.

2 BACKGROUND

Previous research suggests that users navigate best in VEs with locomotion interfaces such as real-walking [23] that provide users with vestibular and proprioceptive feedback. Interfaces that stimulate both of these systems improve navigation performance and are less likely to cause simulator sickness than locomotion interfaces that do not stimulate both systems [2, 23]. VE locomotion interfaces such as walking-in-place, omni-directional treadmills, or bicycles [3, 9] require physical-input from the user, however they do not stimulate the vestibular and proprioceptive systems in the same way as really walking. In contrast, RFED users really walk, generating both vestibular and proprioceptive feedback.

Since user motion must be tracked, VEs using a real-walking locomotion interface have typically been restricted in size to the area of the tracked space. Current interfaces that enable real walking in larger-than-tracked-space VEs include redirected walking (RDW) [18, 19, 20], scaled-translational-gain [21, 31, 32], seven-league boots [10], and motion compression (MC) [13, 27]. Each of these interfaces transforms the VE or user motion by rotating the environment or scaling user motion.

When freely walking in the locomotion interfaces mentioned above, users may find themselves about to walk out of the tracked space, and possibly into a real wall. When a user nears the edge of the tracked space a reorientation technique (ROT) is used to prevent the user from leaving the tracked space [14, 15]. ROTs must be applied before the user leaves the tracked space. ROTs rotate the VE around the user's current location, returning the user's predicted path to the tracked space. The user must also reorient his body by physically turning so he can follow his desired path in the newly-rotated VE.

Redirected Free Exploration with Distractors (RFED) is a locomotion interface that combines transformation of the VE, based on the redirected walking (RDW) system [18], which uses *redirection*—imperceptibly rotating the VE model around the user—to remap areas of the VE to the tracked space, and *distractors*—visual objects and/or sounds in the VE— as a ROT [14, 15].

Transforming the VE by rotation has advantages over other transformations because when people turn their heads at normal angular velocities, the vestibular system dominates the visual system, thus enabling rotation of the VE visuals without the user noticing [6]. As demonstrated by [18], users can be imperceptibly redirected very little unless the redirection is performed while the user's head is turning, which desensitizes the visual system. Additionally, larger amounts of redirection can be imperceptibly accomplished during head turns [11, 18].

To elicit head-turns, RDW used prescribed paths through the VE that at predetermined locations required the user to physically turn her head and body. The principal aim of RFED is to remove this limitation and enable users to walk **freely** about in a VE.

Walking freely in VEs raises a new problem—how to ensure that the user avoids real-space obstacles. Our system uses distractors to guide users away from the tracker boundary. Additionally, we introduce a new technique, *deterrents*—objects in the virtual environment that people stay away from or do not to cross.

While VE transformations, distractors, and deterrents enable large-scale real-walking in VEs, the effect of the transformations on navigational ability is unknown. The study presented in the paper evaluates the effect of rotational transformations and distractions from distractors and deterrents on navigational ability.

3 CONDITIONS

### 3.1 Redirected Free Exploration with Distractors (RFED)

Figure 1: The shaded region represents the real tracked space and the dashed region represents the virtual space. c is in the center of the whole tracked space. We predict the user's future direction, v_{future} and rotate the virtual space such that v_{future} is toward the center of the tracked space, c.

The RFED algorithm presented here is designed based on the Improved Redirection with Distractors (IRD) algorithm presented in [16] and enables free-walking in large-scale VEs as follows:

1. **Predict and Redirect:** At each frame, predict the user's real-space future direction, v_{future} and rotate the VE around the user such that v_{future} is rotated toward c, the center of the tracked space. See Figure 1.

2. **Distract:** Introduce a distractor to:

    1. Stop the user.

    2. Force a head-turn, enabling large amounts of redirection.

    3. Redirect the user's future direction toward the center of the tracked space.

3. **Deter:** If the user is at the boundary, introduce a *deterrent*, objects in the environment that people stay away from or do not cross, to guide the user away from the boundary.

Distractors are used to stop the user when they are near the boundary. We additionally use distractors when the user is away from the boundary to preemptively preemptively increase redirection and redirect the user toward the center of the lab. However, our overall desire is to minimize the number of distractors, since they impair the VE experience. To limit the number of distractions, one wants to redirect as quickly as possible to redirect the user away from the boundary. The two goals of our redirection implementation are to:

- Minimize the total VE redirection used to redirect the user away from the boundary.

- Maximize the instantaneous redirection to quickly redirect the user away from the boundary.

We minimize total redirection by rotating the VE in the direction of the smaller angle between v_{future} and the vector between the user's current position and the center of the tracked space. v_{future} is computed by extrapolation from recent path positions.

If there were no limits to the amount of imperceptible redirection that could occur in any frame, and users were always redirected toward the center of the tracked space, users would never reach a boundary and a distractor would never be introduced. However, there is a limit to the amount of instantaneous redirection that is imperceptible to the visual system.

Results from [11] tell us that the faster the user turns his head, the less aware he will be of VE rotation. Based on that result, we compute θ_{VE}, the amount of rotation that is added to each frame, as a function of ω_{head}, the user's head speed, and a predefined rotation constant, c.

$$|\theta_{VE}| = |\omega_{head}| * c \qquad (1)$$

Based on pilot experiments and results in [11], we chose c to be 0.10 when the VE is rotating in the same direction as ω_{head} and 0.05 when the VE rotates in the direction opposite of ω_{head}.

When redirection fails a **distractor** is used to prevent the user from leaving the tracked space. Our distractor was a hummingbird that flew back and forth in front of the user. See Figure 2 A. The distractor forces user head-turns, thus enabling large amounts of redirection to steer the user back toward the center of the tracked space.

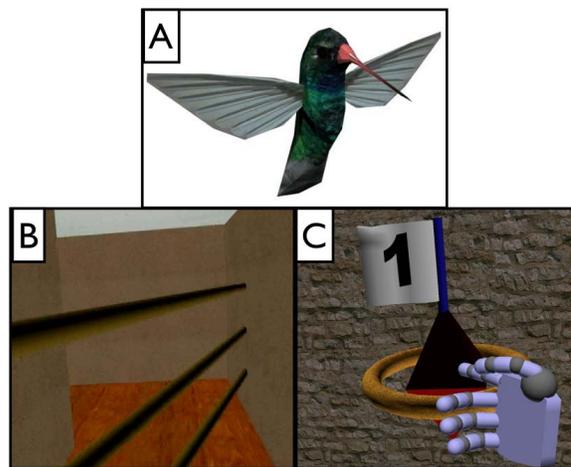

Figure 2: Screen shots of **A:** the hummingbird distractor, **B:** the horizontal bars used as deterrents, and **C:** the virtual avatar hand selecting a target.

If the user is very close to the tracker boundary, we **deter** the user from the boundary with a *deterrent*—an object in the environment

that people are instructed to stay away from or not to cross. For this implementation, deterrents were $6.5m$ virtual horizontal bars that were aligned with the boundaries of the tracked space. Participants were never able to see all of the deterrent bars because the virtual models occluded much of the deterrent model. See Figure 2 B. The bars fade in as the user nears the boundary of the tracked space and fade out as the user walks away from the boundary. The virtual bars provided participants with a visual cue as to which direction to walk to stay in the real space. No participants complained about the bars.

3.2 Walking-In-Place (WIP)

Subjects in the WIP system condition locomoted by stepping in place. Advantages of WIP interfaces include: participants receive kinesthetic feedback from the in-place steps that move the viewpoint, and WIP interfaces can be implemented in small spaces. We used the GUD-WIP locomotion interface, because it closely simulates real-walking [30]. Subjects wore shin-guards equipped with Phase Space beacons and shin position was tracked with a PhaseSpace tracker. See Figure 3. As in [30], heading direction was determined by the participant's average-forward shin direction. Forward speed was a function of shin movement and stepping frequency.

Figure 3: The GUD WIP locomotion interface set-up. Participants were kept in place with the cage make of PVC pipe. The same physical setup was also used in the JS condition.

3.3 Joystick (JS)

Participants in the JS condition controlled forward speed with a hand-held X-Box 360 controller. Deflection of the spring loaded JS controlled speed. The maximum speed of the participant in the joystick condition was chosen to be a moderate walking speed of 3 $miles/hour$. Subjects in the JS condition also used the PhaseSpace tracker to determine heading direction from shin positions. Pushing forward on the joystick translated the participant's viewpoint forward in the average direction of the participant's shins. Virtual movement was restricted to be only in the direction of the participants shins as calculated with the Phase Space beacons.

4 METHODS

The evaluation of RFED compared to WIP and JS required participants to locomote through the virtual mazes shown in Figure 4. The mazes were $15.85m \times 15.85m$, more than twice the dimension (four times the area) of the tracked space. Participants in the RFED condition were restricted to really walking in a space that was $6.5m \times 6.5m$, while participants in the WIP and JS conditions were confined to $1.5m \times 1.5m$ area. See Figure 3.

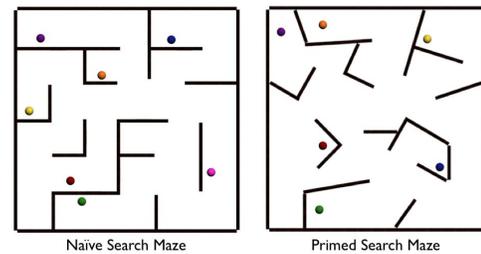

Figure 4: The 15.85m x 15.85m virtual mazes used in this study. Left: the maze used during the naive search with seven targets. Right: the maze used during the primed search with six targets. Participants started each maze in the bottom left corner.

Turning, which stimulates the kinesthetic senses, is believed to aid navigation [2, 23]. Thus, we eliminated turning as a possible confounding factor by requiring users in all conditions to turn, i.e., change heading direction, by physically turning their bodies.

We compared RFED to WIP and JS using navigation and wayfinding tasks: *search* for specified targets within the VE, *point-to-targets* that are not visible, and *map completion*.

Navigation. *Search tasks*, which are commonly used in VE locomotion studies [1], are used to evaluate navigational ability and VE training-transfer of spatial knowledge for locomotion interfaces [29, 33]. Search tasks include *naïve searches*, in which targets have not yet been seen, and *primed searches*, in which targets have previously been seen.

Participants performed both naïve and primed searches. Navigational performance was measured by the total distance participants traveled and the number of times participants revisited routes, i.e., returned to previously visited routes of the virtual mazes.

The distance participants travel is a measure of overall spatial knowledge accuracy [22]. Participants who travel shorter distances tend to have a better spatial understanding of the environment enabling them to walk directly to targets without unnecessarily retracing previous steps.

Wayfinding. *Point-to-target* techniques require participants to point to targets that they have previously seen, but that are currently out of view. Pointing tasks measure a user's ability to wayfind within VEs [2] by testing the user's mental model of target location in relation to the user's current location. Angular pointing errors with small magnitudes suggest that participants have a good understanding of the location of targets.

Map completion requires users to place and label targets on a paper map of the VE after exiting the VE. The map target locations should correspond to VE target locations. Map completion is often used as a wayfinding metric because maps are a familiar navigation metaphor [4]. Participants with a better mental model of the VE can more accurately place targets in correct locations and correctly label targets on the map.

4.1 Participants

Thirty-six participants, 25 men and 11 women, average age 26, participated in the IRB-approved experiment. Twelve participants were assigned to each condition (8 men and 4 women in both RFED and WIP, and 9 men and 3 women in JS).

4.2 Equipment

Each participant wore a stereo nVisor SX head-mounted display with 1280x1024 resolution in each eye and a diagonal FOV of $60°$. The environment was rendered on a Pentium D dual-core 2.8GHz processor machine with an NVIDIA GeForce GTX 280 GPU with

4GB of RAM. The interface was implemented in our locally developed EVEIL intermediate level library that communicates with the Gamebryo® software game engine from Emergent Technologies. The Virtual Reality Peripheral Network (VRPN) was used for tracker communication. The system latency was $50 \pm 5ms$.

The tracked-space was $9m$ x $9m$ and head and hand tracked using a 3rdTech HiBall 3000.

The Walking-in-Place and Joystick systems used an eight-camera PhaseSpace Impulse optical motion capture system with the cameras placed in a circle around the user. The user wore shin guards with seven beacons attached to each shin. PhaseSpace tracked the forward-direction and stepping motion of each leg. The GUD-WIP interface and Joystick direction detection code ran on a PC with an Intel Core2 2.4GHz CPU, NVIDIA GeForce 8600 GTS GPU, and 3 GB RAM.

4.3 Experimental Design

The experimental design is very similar to the study presented in [16]. Participants locomoted through three virtual mazes: a training environment and two testing environments. See Figure 4. The virtual environments were $15.85m \times 15.85m$ mazes with uniquely colored and numbered targets placed at specified locations. See Figure 2 C. All environments used the same textures on the walls and floors, and the same coloring and numbering of targets. The naïve search included seven targets and the primed search included six targets. The VE for the primed search is similar to the naïve search except that the walls are not all placed at 90° angles. This was done to make the experiment more challenging by removing feedback that enables users to determine cardinal directions from axis-aligned walls. The location of the targets changed between the naive and primed searches. All subjects completed the same trials in the same order to control for training effects, and were not given performance feedback during any part of the experiment. Subjects were randomly assigned to the RFED, WIP or JS condition, and completed all parts of the experiment, including training, in the assigned condition.

4.3.1 Training

Subjects received oral instructions before beginning each section of the experiment. The training environment was a directed maze with all walls placed at 90° angles. Subjects walked through the environment pressed a button on a hand-held tracked device to select each of the seven targets which were placed at eye-height and located along the path. Participants had to be within an arm's length to select a target. When a target was selected, a ring appeared around it and audio feedback was played to signify that the target had been found. See Figure 2 C.

After subjects completed the training maze, the head-mounted display was removed and participants were asked to complete a $8.5" \times 11"$ paper map of the environment. The map representation of the environment was a $16cm \times 16cm$ overhead view of the maze with the targets missing. Participants were given their starting location and maps were presented such that the initial starting direction was away from the user. By hand, subjects placed a dot at the location corresponding to each target and labeled each target with its corresponding number or color.

4.3.2 Part 1: Naïve Search

After training, participants were given oral instructions for Part 1, the naïve search. The maze and target locations for Part 1 can be seen in Figure 4. Participants were instructed to, in any order, find and remember the location of the seven targets within the maze. Participants were also reminded they would have to complete a map, just as in the training session. As soon as subjects found and selected all targets, the virtual environment faded to white and sub-

jects were instructed to remove the head-mounted display. Subjects then completed a map in the same manner as in training.

4.3.3 Part 2: Primed Search

After completing the naïve search, subjects were given oral instructions for Part 2, the primed search. The maze and target locations for the primed search can be seen in Figure 4. Participants first followed a directed *priming path* that led to each of the six targets in a pre-specified order. After participants reached the end of the priming path the HMD faded to white, and the participants returned to the starting point in the VE. Participants in the RFED condition had to remove the HMD and physically walk to the starting location in the tracked-space. Participants using WIP or JS were asked if they wanted to remove the HMD, none did, and then they turned in place so they would be facing the starting forward direction in the virtual maze.

Participants were then asked to locomote, as directly as possible, to one of the targets. Once the participant reached and selected the specified target, they were instructed, via audio, to point, in turn, to each of the other targets. The instructions referenced targets by both color and number. After participants pointed to each other target, they were instructed to walk to another target where they repeated the pointing task. If a participant could not find a target within three minutes, arrows appeared on the floor directing the participant to the target. Arrows appeared in 2% of the trials and did not appear more frequently in any one condition. Once the participant reached the target, the experiment continued as before, with the participant pointing to all other targets.

Participants walked to the six targets in the order 3-5-4-1-2-6 and, from each, pointed to each of the other targets in numerical order. At the end of Part 2, subjects had pointed to each target five times, for a total of 30 pointing tasks per subject.

After completing the search and pointing tasks, participants removed the HMD and completed a map just as in Part 1.

After the experiment, subjects completed a modified Slater-Usoh-Steed Presence Questionnaire [24] and a Simulator Sickness Questionnaire [12].
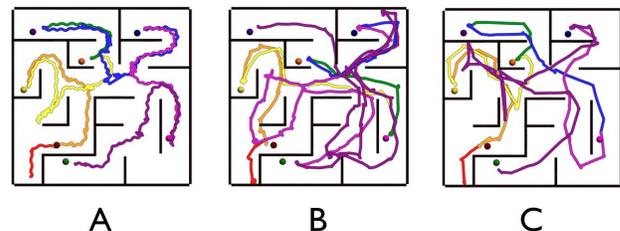

4.4 Results and Discussion

Figure 5: The virtual routes of three participants performing the naïve search, one using each of the three locomotion interfaces. The routes of the participant who traveled the median distance in each locomotion interface is displayed. **A.** RFED. **B.** WIP. **C.** JS.

4.4.1 Part 1: Naïve Search

Navigation Head-position data for all three conditions were filtered with a box filter to remove higher-frequency head-bob components of the signal. The filter width was three seconds. Participant travel distance was calculated from the filtered head pose data. Figure 5 shows the routes of the participant in each condition who's total distance is closest to the median total distance for that condition. Since participants were asked to find all the targets as directly as possible, our hypothesis is that participants who travel shorter distances have a better spatial understanding of the environment
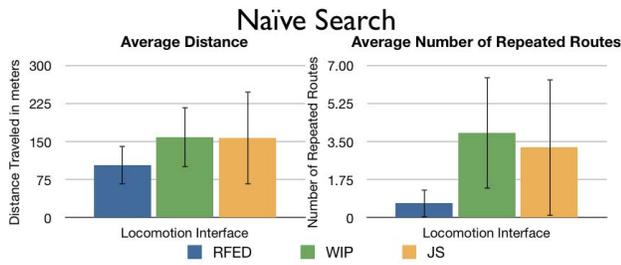

Figure 6: The average total distance traveled and the average number of repeated routes, by locomotion interface, when performing the naive search to find seven targets within the maze, with ±1 standard deviation error bars.

and of previously visited locations. We evaluated the null hypothesis that there was no difference in locomoted distances among locomotion interfaces, Figure 6. We used a Mixed Model ANOVA with locomotion interface as the between-subjects variable and distance traveled as the dependent variable and found a significant difference among locomotion interfaces, $F(2,35)=4.688$, $p=0.016$, $r=0.353$.

We performed Tukey pair-wise, post-hoc tests on the distance traveled data, and applied a Bonferroni correction since multiple Tukey tests were applied on the same data. Bonferroni corrections were applied to all further Tukey pair-wise tests. Participants using RFED traveled significantly shorter distances than participants using either WIP and JS, $p=0.028$ and $p=0.037$ respectively. No significant difference was found in locomoted distance between WIP and JS, $p=0.992$. These results suggest that participants using RFED had a better spatial understanding of the environment.

The number of times participants revisited routes was counted, where a *repeated route* was a route in the maze that a participant walked more than once. See Figure 6. We interpret repeated routes of the maze as indicating that participants were having a harder time building a mental model of the environment. We performed a Kruskal-Wallis test on the number of repeated routes and found a significant difference among locomotion interfaces for the number of times participants repeated routes of the maze when performing a naive search, $H(2)=7.869$, $p=0.02$. Pair-wise comparison post-hoc tests were performed. We found that participants using RFED revisited significantly fewer routes of the maze than participants using WIP, $H(1)=-11.000$, $p=0.026$. This suggests that, participants using RFED were not as lost, or had built a better mental model of the environment than participants using WIP. No significant difference was found comparing RFED to JS, or WIP to JS.

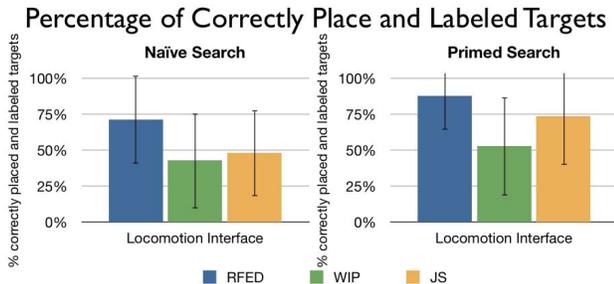

Figure 7: The average percentage of correctly placed and correctly labeled targets on paper maps after completing the naive and primed searches. ±1 standard deviation.

Wayfinding We evaluated participants' ability to place and label each virtual target on a map of the VE. Targets were counted as

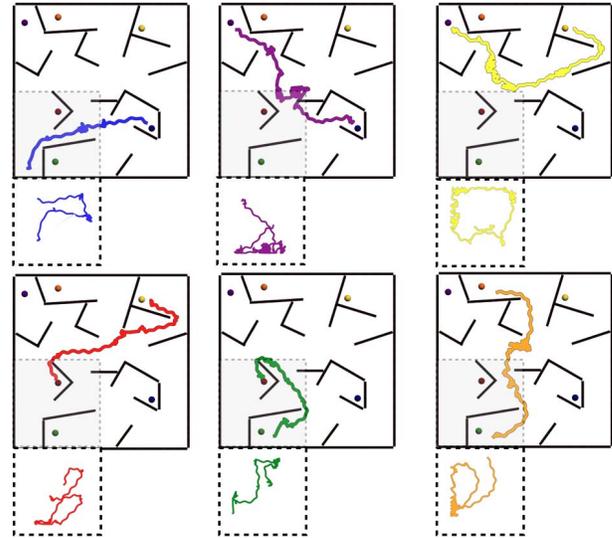

Figure 8: The virtual routes with corresponding real routes taken by a participant in the RFED condition during the primed search part of the experiment. Participants were really walking in one-quarter of the area of the VE. The large boxes are the virtual routes, and the small dashed line boxes are the corresponding real routes. Routes are displayed to scale.

correctly placed if they were within one meter (scaled) of the actual target and on the correct side of walls. Targets were counted as correctly labeled if they were both correctly-placed and were labeled with either the correct number or color. We performed two Mixed Model ANOVAs with locomotion interface as the between-subjects variable and percentage of correctly placed, and correctly-placed-and-labeled targets as the dependent variables. No significant difference was found among locomotion interfaces in user ability to place targets on maps. However, there was a trend that suggest a difference between interfaces on ability to correctly place and label targets after the naive search, $F(2,30)=2.591$, $p=0.092$, $\omega = -0.683$, see Figure 7.

Conclusion The naive search showed RFED participants traveled significantly shorter distances than both WIP and JS participants and revisited significantly fewer routes in the maze than participants using WIP. These results suggest that, when performing a naive search, participants using RFED had a better understanding of where they had already been within the VE and had a better spatial understanding of the VE than participants using either WIP or JS.

4.4.2 Part 2: Primed Search

Navigation We calculated each participant's total travel-distance to find each of the six targets for the primed search, in the same way as the naïve search. The real and virtual routes from an RFED participant can be seen in Figure 8. While each participant travels the directed training path he builds a mental model of the environment. We assert that participants who build a better mental model during priming, i.e., while following the priming path, will locomote shorter distances between targets during the search and pointing portions of the task.

We performed a MANOVA with locomotion interface as the between-subjects variable and distance traveled to each of the six targets as the within-subjects repeated measure. See Figure 9. We

found a significant difference between locomotion interfaces on distance traveled, $F_{(2,32)}=7.150$, $p=0.003$, $r=0.427$. Tukey post-hoc tests show that participants using RFED traveled significantly shorter distances than participants using WIP, $p=0.002$. No other significant results were found. This suggests that participants using RFED were better at navigating the VE than participants using WIP.

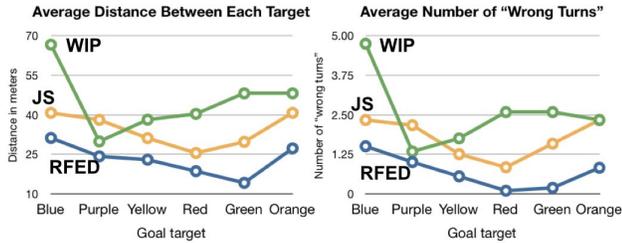

Figure 9: The average distance traveled between targets (in visited order) and the average number of "wrong turns", by locomotion interface when performing the primed search for each of the six targets within the maze.

An additional path evaluation was performed by using a Kruskal-Wallis test on the total number of wrong turns taken by each participant during the primed search. A *wrong turn* occurs at an intersection when the participant does not take the shortest route to the current target goal. A significant difference was found between locomotion interfaces, $H(2)=11.251$, $p=0.004$. Pairwise comparisons, show that participants using RFED made significantly fewer wrong turns than those using either WIP, $H(1)=-13.667$, $p=0.004$, or JS, $H(1)=-10.708$, $p=0.038$. No significant difference was found between JS and WIP users, $H(1)=2.958$, $p=1.00$. These results suggest that participants in RFED had a better understanding of where they were going in the virtual maze and had a better mental model of the environment after having the same experience in the VE as participants in the WIP and JS interfaces.

Analysis of the routes taken to each individual target show significant difference between walking to target #1, the red target, and target #2 the green target, $H(2)=6.505$, $p=0.039$, and $H(2)=8.881$, $p=0.012$ respectively. Post-hoc tests reveal that participants using WIP made significantly more wrong turns when navigating to these two targets than participants using RFED, $H(1)=-9.352$, $p=0.034$, and $H(1)=-11.727$, $p=0.01$ respectively. It is interesting to note that during the priming portion of the task, participants visited target #1, the red target first, and visited target #2 the green target last. This may suggest that participants using WIP have problems in the beginning and end of the VE experience. Note: all subjects had to regularly stop and start locomoting to select the targets as they walked the directed path, and participants had to "walk" to get to target #1. Further evaluation of WIP interfaces should be explored, specifically looking at cognitive load at the beginning and end of a virtual experience. There was no significant difference for any of the individual routes between RFED and JS or WIP and JS.

Wayfinding   During the primed search, when subjects reached a target they then were asked to point to each of the other targets. See Figure 10. Small absolute angular pointing error suggests that participants have a better understanding of the location of targets. We ran a Mixed Model ANOVA with locomotion interface as the between-condition variable and absolute pointing error to each target as the repeated measure. There was a significant difference among locomotion interfaces for the absolute angular error when pointing to targets, $F_{(2,28)}=5.314$, $p=0.011$, $r=0.399$. Tukey pair-wise post-hoc tests reveal that participants using RFED had significantly smaller absolute pointing errors than both WIP and JS, $p=0.021$ and $p=0.024$ respectively. That is, participants using

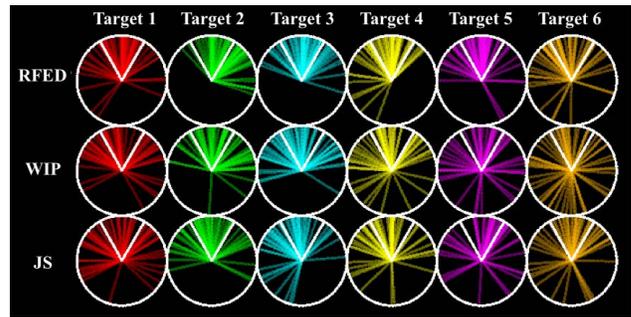

Figure 10: The pointing data for all participants to each of the six targets (columns) by each locomotion interface (row). The white lines denote $\pm30°$.

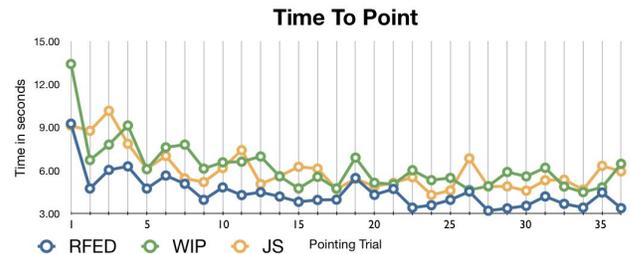

Figure 11: The average pointing time for each pointing trial by locomotion interface.

RFED had significantly better understanding of the location of targets in relation to their current location. There was no significant difference in absolute pointing error between WIP and JS, $p=0.993$.

In addition to evaluating point-to ability, we also analyzed how long participants took to point to each target. See Figure 11. We hypothesized that participants with a clearer mental model would be able to point more quickly to targets. The first pointing trial was also the first time participants pointed, thus we considered this as a training trial and removed it from the data. We ran a Mixed Model ANOVA with locomotion interface as the between-condition variable, and time to point to each target as the repeated measure and found a trend suggesting a difference in pointing time among locomotion interfaces, $F_{(1,19)}=2.992$, $p=0.074$, $r=0.369$.

Further analysis of the first 14 trials, with the first trial removed, shows a significant difference among locomotion interfaces, $F_{(2,23)}=4.636$, $p=0.02$, $r=0.410$. Tukey post-hoc tests show a significant difference between RFED and both WIP and JS, $p=0.031$ and $p=0.050$ respectively. This suggests that participants using RFED had a better mental model when pointing, compared to participants in WIP and JS, during the first half of the primed search. This result may imply that participants using RFED train faster than participants in either WIP or JS conditions, however further studies should evaluate interface training time.

We compared the difference in map completion ability using Mixed Model ANOVAs with locomotion interface as the between-subjects variable and percentage of correctly placed, and correctly-placed-and-labeled targets as the dependent variable, and found a significant difference among interfaces in participant ability to correctly place and label targets, $F_{(2,30)}=3.534$, $p=0.042$, $\omega = -0.603$. See Figure 7. Tukey pair-wise post-hoc tests revealed a significant difference between RFED and WIP in correctly placing and labeling targets on maps after completing the primed search part of the experiment, $p=0.034$. No other significant differences were found.

Table 1: The average VE size estimate and area underestimate by locomotion interface.

Locomotion Interface	Dimension Estimate	Area Underestimate (%)
RFED	15.0 m x 15.0 m	10%
WIP	10.5 m x 10.5 m	56%
JS	9.1 m x 9.1 m	67%
Actual	**15.85 m x 15.85 m**	**0%**

Conclusion The primed search results suggest that participants using RFED navigate and wayfind significantly better than participants using WIP or JS. RFED participants travel shorter distances than participants using WIP, suggesting that RFED participants have a better spatial understanding of the environment and consequently walk more directly to targets. Participants using RFED make fewer wrong turns than either WIP and JS participants, providing additional evidence that RFED participants walk more directly to the goal targets, and hence are better at navigating the environment.

Participants in RFED were significantly better at wayfinding than participants in WIP or JS. RFED participants had significantly smaller absolute pointing errors than those using either WIP and JS. In addition to pointing to targets more accurately, participants using RFED are also better at placing and labeling the targets on maps than participants using WIP. This further suggests that participants in RFED develop a better mental model than WIP participants.

Finally, RFED participants point more quickly to targets in the beginning of the experiment than participants in both WIP and JS, suggesting that participants using RFED build mental models faster, however further studies should be run to verify this result. Overall, participants using RFED point to targets more accurately, complete maps with fewer mistakes, and are quicker at pointing to targets in the first half of the experiment.

4.4.3 Post Tests

After completing the final map, participants were asked to estimate the size of the VEs compared to the size of the tracker space they were currently in. See Table 1. Subjects were told that all three virtual environments were the same size and were given the dimensions of the tracked space. We found a significant difference between VE size predictions based on locomotion condition, $F(2,31)$=6.7165, p=0.006, r=0.742. Tukey pair-wise post-hoc tests reveal differences between RFED and both WIP (p=0.033) and JS (p=0.007). The results suggest that people have a better understanding of VE size when using RFED than with both WIP or JS.

One possible confounding factor was that participants in the RFED condition saw virtual bars in the environment that represented the location of the bounds of the tracked space in the real lab. Based on the design of the maze, participants were not able to see more than 25% of the deterrent boundary at any given instant and usually saw less than 10% of the deterrent boundary. This "real world"-sized reference may have given people in the RFED condition an advantage in estimating the size of the VE. However, two participants in the RFED condition asked to walk around the room before making a guess as to the dimensions of the VE. No participants in JS or WIP asked to walk around the room. This suggests that two participants in the RFED condition realized that their physical walking steps could help measure the size of the VE. The two participants who asked to walk around the room were permitted to walk however neither estimated the lab size significantly better than other participants in the RFED condition.

Presence was evaluated using a modified Slater-Usoh-Steed presence questionnaire [24]. The number of "high" presence scores were counted, scores with a 5 or higher, and a Pearson's chi-square test was performed on the transformed data. No significant difference was found among locomotion interfaces and the number of "high" presence scores, $\chi^2(12) = 14.143$, p=0.292.

Participant simulator sickness scores were calculated using Kennedy's simulator sickness questionnaire [12]. A Pearson's chi-square test was performed on the results. No significant difference was found between locomotion interfaces and simulator sickness scores, $\chi^2(40) = 42.800$, p=0.337.

5 RFED LIMITATIONS

The current RFED implementation is limited by distractors appearing too frequently, a result of participants reaching the edge of the tracked space too often. In the current implementation, on average a distractor appears after the participant travels $5m \pm 4m$ and remains visible for $8s \pm 2s$. However, participants often travel longer distances than $5m$ before being stopped by a distractor. Once the participant stops, 2 or 3 distractors occasionally appear before the participant is redirected to the center of the tracked space and resumes walking.

The frequent occurrence of distractors is an obvious drawback of the current implementation. Improving the current redirection design and implementation, as well as determining how to encourage users to turn their heads, will reduce the occurrence of distractors and deterrents and the number of times participants reach the boundary of the tracked space.

Additionally, the implementation of RFED requires a large tracked area to enable redirection. With an average step length of $0.75m$, in four steps a person can travel $3m$, a typical tracking width. Although it is currently unknown as to how much redirection can be added at any instant, results from [11] suggest that, with head turns, the virtual scene can rotate $1.87°/sec$ and [26] suggests that people can be reoriented up to $30°$ when performing a $90°$ virtual rotation, i.e., the rotation could be $60°$ or $120°$. From observation, if a person is walking straight and not turning their head, very little unobservable redirection can be added to the scene. Therefore, in a $3m x 3m$ tracked space, the user may have to be stopped every 4 or 5 steps.

6 CONCLUSION

This study shows that RFED is significantly better than walking-in-place based on the same navigation metrics that were used in [16]. Researchers have shown that walking interfaces are significantly superior to joystick interfaces on many kinds of measures [33, 28]. Trends have been seen suggesting that real walking is superior to walking-in-place but no previous results have been able to show a statistically significant superiority. The study presented in this paper does that. We used a WIP system, GUD-WIP that is state-of-the-art [30]. We developed a real-walking system, RFED, that enabled free exploration of larger-than-tracked-space virtual environments. Pairwise comparisons showed that RFED was significantly superior to GUD-WIP and a JS interface on several navigation measures. Moreover, RFED was never significantly worse than either the JS and WIP interfaces on any measured metric in this study.

Further, we found no significant differences between our JS implementation and GUD-WIP. This was a surprising result, as we expected GUD-WIP to out-perform JS. We believe one reason for the lack of a significant differences stems from the challenges of stopping and starting in WIP systems, including GUD-WIP. The virtual mazes required many starts and stops to select and point to targets and WIP participants occasionally walked through targets when trying to stop in front of them. Additionally, when starting to walk, participants intentionally "walked" through targets in both JS and WIP interfaces instead of walking around them, while RFED participants did not walk through targets.

Although we found no navigational difference between WIP and JS, our results further support that real walking is critical for navigating VEs. Even though RFED continuously rotates the virtual world around the user and frequently stops the user with distractors, RFED participants were significantly better at navigating VEs than both WIP and JS participants. The physical difference between the systems is the stimulation of the proprioceptive system. There was no kinesthetic difference between interfaces since heading direction was controlled by physical heading direction. Although WIP stimulates the proprioceptive system, RFED more accurately stimulates the proprioceptive system because it is more similar to real-walking.

Our results support that accurate stimulation of the proprioceptive system is critical to navigation and even with rotation of the VE around the user and distractors, participants were able to navigate VEs significantly better than without accurate proprioceptive stimulation. Further development of RFED and RFED-like systems to improve usability will further aid VEs and the intended goal of free exploration of large spaces without user awareness of the enabling techniques.
